

Week 22: Project Implementation – Backend APIs

1. Complete REST APIs

Backend APIs were developed to handle all core application features. REST APIs allowed communication between client and server using methods like GET, POST, PUT, and DELETE. These APIs managed user data and application functionality efficiently.

2. Authentication and Authorization

Authentication was implemented to verify users through secure login systems. Authorization controlled access to protected resources and routes. Features like JWT-based authentication improved security and access control.

3. Validation, Error Handling, Logging

Validation ensured only correct input data was processed. Error handling prevented server crashes and returned proper responses. Logging helped track application events and debug issues during development.

4. Testing with Postman

Postman was used to test API endpoints and verify request-response functionality. It helped check authentication, CRUD operations, and error handling. This ensured API reliability before frontend integration.

Conclusion

This week focused on backend API development. By building REST APIs, implementing authentication, handling errors, and testing with Postman, a reliable backend system was created.
